1 Abstract

As most of the countries, Switzerland is growing. Cities are getting more inhabitants, growing together or arising new. With more people living in the cities and generally in Switzerland, more people will use the public transport system and the railroad network has to grow and develop. In this case, the main goal of this project is to simulate the Swiss railroad network depending on population growth to see where the systems should be improved.

The network is simulated like a biological model, based on *Physarum polycephalum*. This slime mold is a large single-celled amoeboid organism that forages for food sources. To maximize the searched area, it explores its environment with a relatively continuous foraging margin. It's forming different junctions and nodes to reduce the overall length of the connecting network [2]. And this principle is adapted to the main transport lines in Switzerland.

3 Introduction and Motivations

4 Description of the Model

The model is inspired of the *physarum polycephalum* and the way it's searching for food. The organism have been subjected to successive rounds of evolutionary selection and have found an appropriate balance between efficiency, cost and resilience. The plasmodium contains a network of tubes, which enables chemical signals and nutrients to circulate through the organism. If some of the tubes have found food sources, this implies a positive feedback to the system. This tubes are getting thicker so the flux of nutrients increase. Other tubes which don't connect to a food sources are shrinking and tend to disappear. because there is no flux available. Experiments showed two empirical roles. First tubes with no connection to a source disappear and second, if there are two tubes connecting the same source, the longer one disappears. This led to useful approaches to problem-solving like optimization of railroad systems or networks in general.

The mathematical model is based on *Physarum solver: A biologically inspired method of road-network navigation* [1]. Figure 1 shows the concept of the mathematical model. There are different nodes. First two nodes corresponding to the food sources (N_1 and N_2) and other nodes ($N_3, N_4 \dots N_j$). The junction between the node N_i and N_j is denoted as M_{ij} .

Figure 1: Concept of the mathematical model. Squares represent ordinary nodes, circles represent food sources, each line represent a junction

The variable Q_{ij} stands for the flux through the junction M_{ij} from N_i to N_j . The flux Q_{ij} is given by an approximately Poiseuille flow where p_i is a pressure at the node N_i , L_{ij} is the length and D_{ij} is the conductivity of the junction M_{ij} :

$$Q_{ij} = \frac{D_{ij}}{L_{ij}} (p_i - p_j) \quad (1)$$

By considering Kirchhoff's law at each node, there is:

$$\sum_i Q_{ij} = 0 \quad \text{if } (j \neq 1, 2) \quad (2)$$

N_1 is assumed as a source node and N_2 as a sink and I_0 represent the flux from the source node and is in this model constant. It followed:

$$\sum_i Q_{i1} + I_0 = 0, \quad \sum_i Q_{i2} - I_0 = 0 \quad (3)$$

To describe the thickness of the junctions we assumed that the conductivity D_{ij} changes in time according to the flux Q_{ij} :

$$\frac{dD_{ij}}{dt} = f(|Q_{ij}|) - D_{ij} \quad (4)$$

where $f(|Q|)$ is a increasing function with $f(0) = 0$. Here $f(|Q|)$ is given by:

$$f(|Q|) = \frac{|Q|^\gamma}{1 + |Q|^\gamma} \quad (5)$$

The network Poisson equation for the pressure is derived from the equations (1), (2) and (3) as followed:

$$\sum_i \frac{D_{ij}}{L_{ij}} (p_i - p_j) = \begin{cases} -I_0 & \text{for } j = 1, \\ I_0 & \text{for } j = 2, \\ 0 & \text{otherwise} \end{cases} \quad (6)$$

All p_i 's can be determined by solving the equation system (6) wenn setting $p_2 = 0$ as a basic pressure level. With this also each Q_{ij} is obtained. They're definend bay the D_{ij} 's and L_{ij} 's at each time step. Conductivity is closely related to the thickness of the junctions and so when a conductivity of a junction is zero, it disappears.
